**Introduction**

Driven by the need for untethered mobility and ease of use, many systems rely on rechargeable batteries as their primary power source. The battery charger is typically implemented using a fixed-function IC to control the charging current/voltage profile.

The C8051F300 family provides a flexible alternative to fixed-function linear battery chargers. This note discusses how to use the C8051F300 device in Li-Ion battery charger applications. The Li-Ion charging algorithms can be easily adapted to other battery chemistries.

The code accompanying this application note was originally written for C8051F30x devices. The code can also be ported to other devices in the Silicon Labs microcontroller range.

**Key Points**

- On-chip high-speed ADC provides superior accuracy in monitoring charge voltage (critical to prevent overcharging in Li-Ion applications), maximizing charge effectiveness and battery life.
- On-chip comparator and PWM provides a means to implement a high speed buck converter with a small external inductor.
- On-chip temperature sensor provides an accurate and stable drive voltage for determining battery temperature. An external RTD (resistive temperature device) can also be accommodated.
- A single C8051F300 provides full product range for multi-chemistry chargers, expediting time to market and reducing inventory.

**Charging Basics**

Batteries are exhaustively characterized to determine safe yet time-efficient charging profiles. The optimum charging method for a battery is dependent on the battery’s chemistry (Li-Ion, NiMH, NiCd, SLA, etc.). However, most charging strategies implement a 3-phase scheme:

1. Low-current conditioning phase
2. Constant-current phase
3. Constant-voltage phase/charge termination

![Figure 1. Lithium Ion Battery Charger Block Diagram.](image-url)
All batteries are charged by transferring electrical energy into them. The maximum charge current for a battery is dependent on the battery’s rated capacity (C). For example, a battery with a cell capacity of 1000mAh is referred to as being charged at 1C (1 times the battery capacity) if the charge current is 1000mA. A battery can be charged at 1/50C (20 mA) or lower if desired. However, this is a common trickle-charge rate and is not practical in fast charge schemes where short charge-time is desired.

Most modern chargers utilize both trickle-charge and rated charge (also referred to as bulk charge) while charging a battery. The trickle-charge current is usually used in the initial phases of charging to minimize early self heating which can lead to premature charge termination. The bulk charge is usually used in the middle phase where the most of the battery’s energy is restored.

During the final phase of battery charge, which generally takes the majority of the charge time, either the current or voltage or a combination of both are monitored to determine when charging is complete. Again, the termination scheme depends on the battery’s chemistry. For instance, most Lithium Ion battery chargers hold the battery voltage constant, and monitor for minimum current. NiCd batteries use a rate of change in voltage or temperature to determine when to terminate.

While charging, some of the electrical energy is converted to thermal energy, until the battery reaches full charge, at which time all the electrical energy is converted to thermal energy. If charging isn’t terminated, the battery can be damaged or destroyed. Fast chargers (chargers that charge batteries fully in less than two hours) compound this issue, as these chargers use a high charge current to minimize charge time. Therefore, monitoring a battery’s temperature is critical especially for Li-Ion batteries which may explode if overcharged. Temperature is monitored during all phases and charge is terminated immediately if the temperature exceeds a preset maximum limit.

Hardware Description

Li-Ion batteries are currently the battery chemistry of choice for most applications due to their high energy/space and energy/weight characteristics when compared to other chemistries. Most modern linear Li-Ion chargers use the tapered charge termination, minimum current (see Figure 2) method to ensure the battery is fully charged, as does the example code provided at the end of this application note.

Buck Converter

The most economical way to create a tapered termination linear charger is to use a buck converter. A buck converter is a switching regulator that uses an inductor and/or a transformer (if isolation is desired), as an energy storage element to transfer energy from the input to the output in discrete packets. Feedback circuitry regulates the energy transfer via the transistor, also referred to as the pass switch, to maintain a constant voltage or constant current within the load limits of the circuit.
Figure 2. Lithium Ion Charge Profile.

![Lithium Ion Charge Profile Diagram](image)

Figure 3. Buck Converter.

![Buck Converter Diagram](image)

- **Switch ON**
- **Switch OFF**

Switch ON when `VBatt < VREF`

Switch OFF when `VBatt > VREF`
**Buck Regulator Operation**

The buck regulator operates by controlling the duty cycle of a transistor switch. The duty cycle is automatically increased to dispense more current into the battery. A comparator closes the switch when \( V_{BATT} < V_{REF} \). As shown in Figure 3a, current flows into the battery and capacitor C. This current is also stored in inductor L. \( V_{BATT} \) rises until it exceeds \( V_{REF} \) at which time the comparator turns the switch off (Figure 3b). The current stored in the inductor rapidly decreases until diode D is forward biased, causing inductor current to flow into the battery at a decreasing rate. Capacitor C begins discharging after the inductor current has decayed and eventually \( V_{BATT} \) begins to fall. When \( V_{BATT} \) falls below \( V_{REF} \), the comparator again turns the switch on and another cycle begins. On a larger scale, if the duty cycle is decreased (shorter “on” time), the average voltage decreases and vice versa. Therefore, controlling the duty cycle allows one to regulate the voltage or the current to within desired limits.

**Selecting the Buck Converter Inductor**

To size the inductor in the buck converter, one first assumes a 50 percent duty cycle, as this is where the converter operates most efficiently.

Duty cycle is given by Equation 1, where \( T \) is the period of the PWM (in our example \( T = 10.5 \mu S \)).

\[
\text{DutyCycle} = \frac{\text{ton}}{T}
\]

*Equation 1. Duty Cycle.*

With this established, select a PWM switching frequency. As Equation 2 shows, the larger the PWM switching frequency, the smaller (and more cost effective) the inductor. Our example code configures the ‘F300’s hardware to generate a 510kHz switch rate.

\[
L = \frac{(V_i - V_{sat} - V_o)\text{ton}}{2I_{omax}}
\]

*Equation 2. Inductor Size.*

Now we can calculate the inductor’s size. Assuming \( V_i \), the charging voltage, is 15V, \( V_{sat} \), the saturation voltage, is 0.5V, the desired output voltage, \( V_o \), is 4.2V, and \( I_{omax} \), the maximum output current, is 1500 mA, the inductor should be at least 4\( \mu \)H.

Note that the capacitor in this circuit is simply a ripple reducer. The larger it is the better as ripple is inversely proportional to the size of the capacitor.

**High Speed Charger**

As AN037, *Lithium Ion Battery Charger Using C8051F300*, illustrates, the F300’s 8-bit PWM can be configured to generate a 96kHz PWM with no external components. This PWM output can be used to drive the pass switch in a buck converter and charge a battery. However, a 96kHz frequency requires a buck converter to utilize a relatively large 18\( \mu \)H inductor. For some applications, this is too large and costs too much. To reduce the size and cost of this inductor requires that the switch rate of the buck converter increase. The beauty of the F300 lies in its flexible feature set. As mentioned, included in the device is a PCA (Programmable Counter Array) that has three 16-bit capture/compare modules with corresponding output drives that can be configured to provide numerous functions. We can use two of the PCA’s modules, along with two external single-pole low-pass filters, and the on-chip comparator to generate an 8-bit, 510kHz PWM (refer to Figure 4 for details). By setting the switch rate to 510kHz, the inductor required to satisfy the buck converter equations is reduced by a factor of five to approximately 4\( \mu \)H.
To create a 510kHz PWM with the F300, Module 0 of the PCA is configured to provide a 510kHz square wave via the Frequency Output Mode. This square wave is then filtered through a low-pass filter with a 500kHz corner frequency to provide approximately a 2 Volt peak-to-peak pseudo triangle wave to the positive input of the on-chip comparator. For the minus input of the comparator, Module 1 is configured as an 8-bit PWM at 96kHz switch rate. This PWM output is then low pass filtered with a corner frequency of approximately 15Hz to create a simple DC digital-to-analog converter. By comparing the pseudo triangle wave to a DC input, the output of the comparator’s output becomes a 510kHz PWM.

The DC control path, Module1’s output in this example, controls the duty cycle of the 510kHz PWM output from the comparator. By varying the duty cycle of the 8-bit 96kHz PWM, the minus input to the comparator can be varied from 0 volts to the supply, typically 3.3V. The accuracy of the DC control path is limited by the settling time of the external RC filter. For this example, components were selected to minimize errors contributed from this path. For more details on component selection for the DC path, refer to AN010, 16-Bit PWM Using an On-Chip Timer.

The overall accuracy of the 510kHz PWM output from the comparator is mostly limited by the pseudo triangle path to the comparator. Assuming the DC path is error free, to create a true 8-bit 510kHz PWM output from the comparator requires that a perfectly linear full-scale triangle wave be input to the positive input of the comparator. A true full scale triangle wave refers to a triangle wave that linearly ramps from 0 volts to the positive supply and then returns back the negative supply in a similar fashion. However, the charge and discharge profile of a capacitor in the low pass configuration is not linear past a time constant. Moreover, it is desirable not to allow this capacitor to fully charge as the pseudo triangle wave becomes more non-linear towards its peaks. Unfortunately, limiting the overall charge time/voltage limits the overall accuracy of the 510kHz PWM. For example, if we compare a triangle wave with a peak-to-peak voltage of 1/4 the supply to the DC control path’s voltage, we could generate a 2-bit 510kHz PWM output from the comparator. In practical applications, a 2-bit 510kHz has very limited use. To improve the accuracy requires either one of two changes: 1) increase the voltage of the pseudo triangle wave or 2) increase the resolution of the DC path’s PWM control. As mentioned earlier, increasing the peak-to-peak voltage of the pseudo triangle wave can be easily accomplished by adjusting its low pass filter components accordingly. Our example is designed

Figure 4. High Speed Charger.
to provide approximately a 2 volt peak-to-peak pseudo triangle wave. When compared to the 8-bit PWM dc control path, we achieve approximately 7.5-bits of performance at 510kHz switch rate.

The overall resolution of the high speed PWM output can be increased very easily by configuring Module 1 to a 16-bit PWM. On an aside, if a faster PWM output, greater than 510kHz, is desired to reduce the inductor size further, the user can reconfigure Module 0 to provide a faster square wave up to $\frac{1}{2}$ the internal oscillator frequency or approximately 12MHz. If this is desired, the external low pass filter for the pseudo triangle wave path will have to be modified to accommodate the faster square wave. Other limitations, like comparator speed and voltage induced across the inductor due to the higher current transients will also have to be considered.

Software Description

The software example that follows demonstrates a Li-Ion battery charger using the C8051F300. The algorithms discussed are written entirely in “C” making them easily portable. Refer to the F300’s datasheet for a full description of the device. Note that the software architecture for the low speed (96kHz) charger discussed in AN037 and the high speed charger (510kHz) are essentially the same (i.e. the flow charts that follow can be used for either hardware configuration). The main difference are the control mechanisms. For the slow speed charger in AN037, Module 0 (CEX0) is used to control the duty cycle. For the high speed charger Module 1 (CEX1) is used to control the duty cycle.

Calibration

To ensure accurate voltage and current measurements, the algorithms use a two-point system calibration scheme. In this scheme, the user is expected to apply two known voltages and two known currents, preferable, one point near ground and the other point near full-scale. The algorithm then takes these two points, calculates a slope and an offset for both the current and voltage channels, and stores the results in FLASH. All future conversions are scaled relative to these slope and offset calculations.

Temperature

To monitor the temperature, the algorithms use the on-chip temperature sensor. The sensor is left uncalibrated, but still provides a sufficiently accurate temperature measurement. For more accurate temperature measurement, one or two-point temperature calibration is required.

An external temperature sensor can be used if desired. The AMUX can be reconfigured to accommodate this additional input voltage.

Current

The current delivered to the battery cells is monitored by measuring the voltage across a sense resistor (typically tens of ohms; our example uses a 0.24 ohm resistor). To maximize current measurement accuracy, this reference design uses an external amplifier with a gain of 10. This provides about 11-bits of current measurement accuracy (8-bits from the ADC and 3-bits from the external gain amplifier). To further maximize current measurement accuracy, the raw current measurements are scaled via the slope and offset calibration coefficients every time a measurement conversion is taken.

To determine the minimum current resolution, recall that the output code of a ADC is given by

$$Dout = \frac{(Ain)2^n}{Vref}$$

Accounting for the external amplifier, Equation 4

\[ \text{Ain} = (\text{Iin} \times \text{Rs} \times 10) \]

Equation 4. Input Current with 10x Gain.

states that Ain is

Iin is then given by Equation 5

\[ \text{Iin} = \frac{(\text{Dout} \times \text{Vref})}{2^n \times 10 \times \text{Rs}} \]

Equation 5. Input Current.

Assuming

- \( \text{Rs} = 0.24 \Omega \)
- \( \text{VREF} = 3.3 \text{ V} \)
- \( 2^N = 256, \text{ an 8-bit converter} \)
- \( \text{External Gain} = 10 \)
- \( \text{No External Gain} = 1 \)

When Dout = 1, I_{\text{MIN}} is given by Equation 6.

\[ \text{I_{MIN}} = (5.37) \frac{\text{mA}}{\text{Code}} \]

Equation 6. I_{\text{MIN}}.

When Dout=256, Imax is given by Equation 7.

\[ \text{I_{MAX}} = (1.37) \text{Amps} \]

Equation 7. Imax.

It is important to note that if one chooses to modify the algorithm, the order of mathematical operations is important. To minimize truncation error effects, be sure to perform multiply operations first making the numerator as large as possible, before performing divide operations. Further recall that a long type variable, which is the limit for the F300’s compiler, is limited to \( 2^{32} - 1 \) or approximately 4 billion.

**Voltage**

The battery’s voltages are divided down and monitored via external resistors. Note that this example uses the supply voltage as the ADC voltage reference. Any monitored voltage above the reference voltage must be divided down for accurate monitoring. If a more accurate reference is required, an external voltage reference can be used. Adjustment to the divide resistors must be made accordingly.

**Charging - Phase 1**

In Phase 1, (for description purposes, we assume the battery is initially discharged), the ‘F30x regulates the battery’s current to I_{LOWCURRENT} (typically 1/50 C) until the battery’s voltage reaches V_{MINVOLTBULK}. Note that the battery’s charge current is current limited to I_{LOWCURRENT} to ensure safe initial charge and to minimize battery self-heating. If at any time the temperature increases out of limit, charging is halted.

**Charging - Phase 2**

Once the battery reaches V_{MINVOLTBULK} the charger enters Phase 2, where the battery’s algorithm controls the PWM pass switch to ensure the output voltage provides a constant charge-current I_{BULK} to the battery (rate or bulk current is usually 1C and is definable in the header file as is I_{LOWCURRENT} and V_{MINVOLTBULK}).

**Charging - Phase 3**

After the battery reaches V_{Top} (typically 4.2 V in single cell charger), the charger algorithm enters Phase 3, where the PWM feeds back and regulates the battery’s voltage. In Phase 3, the battery continues to charge until the battery’s charge current reaches I_{MINIBULK}, after which, the battery is charged for an additional 30 minutes and then charge terminates. Phase 3 typically takes the majority of the charging time.
Note that in most practical applications, such as a portable PC, the batteries may be in any of the three phases when charging is activated. This doesn’t really affect the charger as it simply monitors the battery’s current condition and starts charging from that point.

**Getting Started**

The reference design that accompanies this application note is designed to charge a single cell 4.2 V lithium ion battery. To accommodate numerous power supplies and batteries, it charges at 250mA bulk current. To charge a battery, first connect power to the board by applying an 8V to 15V supply to JP1. The power supply should be able to supply a minimum of 500mA. Once the appropriate supply is connected, connect the battery to JP3. Connect the positive lead of the battery to pin 1 and connect the negative lead to pin 3. Terminal 2 of JP3 can be left unconnected as no code has been developed to monitor temperature via an external temperature sensor at this time. Finally, press the reset switch and the battery will begin charging. The PWM charge control signal can be monitored by probing pin 5 on the C8051F300.

To charge more than 1 battery cell, both the hardware and software will need to be modified. For example, to charge two 4.2 V batteries simultaneously, resistors R11 and R12 will need to be switched. Then, the header file will need these modifications:

```
CELLs = 2
RESB = 10
```

Once the header file is modified, recompile the software and download the new source code to the charger board. A similar scheme can be used to modify the board for any number of cells.

**Conclusion**

The C8051F300’s high level of analog integration, small form-factor, integrated FLASH memory, and low power consumption make it ideal for flexible next generation battery charging applications. This note discussed how to use the C8051F300 in Lithium Ion battery charger applications at 510kHz switch rate. Example code is provided as well.
